Gastric CT Findings

Summary of a published patient case

Adapted for the app demonstration; this is not the original hospital radiology report.

Clinical context

A 68-year-old man underwent contrast-enhanced abdominal CT during investigation of anemia.

Initial CT findings

The stomach antrum and pylorus had irregular circumferential wall thickening measuring up to 1.9 cm. The abnormal tissue enhanced progressively after contrast. The initial scan showed no liver metastases or significantly enlarged abdominal lymph nodes.

Diagnostic confirmation

Endoscopic biopsy established AFP-producing hepatoid adenocarcinoma of the stomach. This diagnosis came from tissue examination, not CT alone.

Later imaging

Follow-up CT after gastric surgery showed new lesions in the right liver. Subsequent tissue examination confirmed metastatic disease. These later findings belong to a different time point from the initial scan.
